## Résumé de l'article

In this paper we study the selection of the number of primitive shocks in exact and approximate factor models in the presence of structural instability. The empirical analysis shows that the estimated number of factors varies substantially across several selection methods and over the last 30 years in standard large macroeconomic and financial panels. Using Monte Carlo simulations, we suggest that the structural instability, expressed as time-varying factor loadings, can alter the estimation of the number of factors and therefore provides an explanation for the empirical findings.

# SELECTION OF THE NUMBER OF FACTORS IN PRESENCE OF STRUCTURAL INSTABILITY: A MONTE CARLO STUDY* 

Charles Olivier MAO TAKONGMO<br>Department of Economics<br>McGill University<br>maotcharles@yahoo.fr<br>Dalibor STEVANOVIC<br>Département des sciences économiques<br>Université du Québec à Montréal<br>dstevanovic.econ@gmail.com

AbSTRACT-In this paper we study the selection of the number of primitive shocks in exact and approximate factor models in the presence of structural instability. The empirical analysis shows that the estimated number of factors varies substantially across several selection methods and over the last 30 years in standard large macroeconomic and financial panels. Using Monte Carlo simulations, we suggest that the structural instability, expressed as time-varying factor loadings, can alter the estimation of the number of factors and therefore provides an explanation for the empirical findings.

## Introduction

Following the improvement of information technology, large panels of economic and financial time series are now available. Using a large data set in econometric analysis can lead to the curse-of-dimensionality problem. One such example is the rise in degrees-of-freedom when the number of variable increases. On the other hand, choosing among variables introduces an element of arbitrariness and can lead to misspecification and misleading results (see Hansen and Richard, 1987; Ludvigson and $\mathrm{Ng}, 2007$ ). A solution to this problem is to use the factor analysis where the information in hundreds of economic and financial time series can be

[^0]summarized by a relatively small number of (common and latent) factors (see, among others, Chamberlain and Rothschild, 1983; Connor and Korajczyk, 1986, 1988, 1993; Chen, Roll and Ross, 1986; Stock and Watson, 2002; Bernanke, Boivin and Eliasz, 2005; Ludvigson and Ng, 2007, 2009, 2011).

The existence of the factor model is strictly related to the number of primitive shocks in a data set (Rao, 1955). The choice of the number of factors is very important. In fact, researchers can face misspecification problems when the number of factors is underestimated, or problems related to power when the number of factors is overestimated. Many methods have been proposed to estimate the number of (static and dynamic) factors (see, among others, Bai and Ng, 2002, 2007; Onatski, 2009, 2010; Alessi, Barigozzi and Capasso, 2010; Ahn and Horenstein, 2013; Hallin and Liska, 2007; Amengual and Watson, 2007).

The aim of this paper is to study the performance, in terms of the selection of the number of factors, of different tests and information criteria in the context of structural instability. First, we conduct an extensive comparison of all the procedures using several large macroeconomic and financial panels. The empirical results shows that: i) the estimated number of factors differs substantially across the selection methods; ii) it varies a lot over time across, and within, selection methods. Several explanations are possible. The factors (often perceived as states of economy) become more or less pervasive over time such that their dimension can be harder to estimate. The structural changes, such as adoption of new monetary and fiscal policies, can affect the way observable series load on the factors.

In the second part of the paper, we perform many Monte Carlo simulations to suggest that the structural instability can alter the estimation of the number of factors and therefore explain the empirical findings above. In particular, we approximate the structural changes by allowing for time-varying factor loadings. Our work is related to Bates, Plagborg-Moller, Stock and Watson (2013), BPSW hereafter, who consider the estimation of the factor space in the presence of time variation in factor loadings. They also verify the performance of the Bai and Ng (2002) criterion to successfully predict the dimension of the factor space. The second related paper is Chen, Dolado, and Gonzalo (2014), who provide a framework to test for large breaks in factor loadings'. They also show that the Bai and Ng (2002) information criteria are likely to overestimate the true number of factors in the presence of large breaks. Finally, Guo-Fitoussi and Darné (2014) concentrate on comparing finite sample properties among many selection rules. Our contribution to this literature consists of: i) providing empirical evidence for the time varying factor structure, in terms of the number of factors, in macroeconomic and large financial data sets; ii) assessing the performance of several selection rules in the presence of irregularities discussed above. In addition, we study the robustness of selection methods in small and large samples, and in exact and approximate factor structures.

1. See also Breitung and Eickmeier (2011) who test for the presence of structural breaks in dynamic factor models.

The results from our extensive simulation exercise show that structural instabilities, taking several forms of time-variant factor loadings, together with cross-sectional and time dependence of the idiosyncratic component, do alter the estimation of the number of factors across all six most popular selection methods used in the literature. These results can provide an explanation to the empirical evidence on large volatility in the estimated number of factors.

In the first section, we present the time-varying parameters factor model framework. The selection rules considered in our analysis are shown in Section 2. The empirical part of the paper is presented in Section 3. The Monte Carlo simulation experiments are detailed in Section 4. Additional empirical results are presented in the Appendix.

## 1. The Factor Model

In this framework, the large number of observed time series are modelled as dependent on a small number of latent factors. The factor model can be written as follows:

$$
\begin{equation*}
X_{i, t}=\lambda_{i, t}^{\prime} F_{t}+e_{i, t}, \quad i=1, \ldots, N \quad t=1, \ldots, T \tag{1}
\end{equation*}
$$

where $X_{i, t}$ is the observed data, $\lambda_{i, t} \in \mathbb{R}^{q}$ is the possibly time varying factor loading, $F_{t}$ is a $q \times 1$ vector of latent common factors and $e_{i, t}$ is an idiosyncratic error assumed to be uncorrelated with $F_{t}$ at all leads and lags.

Define $\quad \mathbf{X}_{\mathbf{t}}=\left(\mathrm{X}_{1, \mathbf{t}}, \ldots, \mathbf{X}_{N, t}\right)^{\prime}, \quad \wedge_{\mathbf{t}}=\left(\lambda_{1, t}, \ldots, \lambda_{N, t}\right)^{\prime}, \quad \mathbf{e}_{\mathbf{t}}=\left(\mathrm{e}_{1, t}, \ldots, \mathrm{e}_{N, t}\right)^{\prime}$, and $\mathbf{F}_{\mathbf{t}}=\left(\mathrm{F}_{1, \mathbf{t}}, \ldots, \mathrm{~F}_{q, t}\right)^{\prime}$ such that the model can be written in a more compact form:

$$
\begin{equation*}
X_{t}=\wedge_{t} F_{t}+e_{t} \tag{2}
\end{equation*}
$$

Following BPSW the structural instability may be introduced by modelling the factor loadings as follows:

$$
\begin{equation*}
\wedge_{t}=\wedge_{0}+h_{N T} \zeta_{t}, \tag{3}
\end{equation*}
$$

where $h_{N T}$ is a deterministic scalar sequence that may depend on $N$ and $T . h_{N T}$ sets the scale of deviation. $\zeta_{t}$ is a possibly random process of dimension $N \mathrm{x} r . \zeta_{t}$ will be modelled depending on which type of instability we want to assess. For example, $\zeta_{t}$ may be white noise, in which case the factor loading $\wedge_{t}$ will be the initial loading matrix $\wedge_{0}$ plus uncorrelated noise. $\zeta_{t}$ may also be modelled as a random walk, which gives a standard continuous time-varying parameter model. Finally, $\zeta_{t}$ may be a single deterministic break. Of course, if $\wedge_{t}$ is constant, (1) becomes standard factor model with constant parameters.

Note that we only consider the time instability in factor loadings and do not specify a time-varying VAR process for factors, unlike in Korobilis (2013) and Eickmeier, Lemke and Marcellino (2014). Our goal is not to study how impulse responses of $X_{t}$ are changing over time, but to verify if the estimation of the number of factors is affected by structural instabilities in the way the observable series are linked to latent states of the economy.

## 2. Tests and Criteria for Selecting the Number of Factors

We consider several selection methods that have been recently developed in approximate static linear factor model framework. In this section, they are presented briefly, the details can be found in the original references. Information criteria procedures are represented by Bai and Ng (2002) and Amengual and Watson (2007). Onatski (2010) and Ahn and Horenstein (2013) are tests based on the theory of random matrices, while Bai and Ng (2007) exploit the rank of matrices. Finally, Hallin and Liska (2007) build on spectral density representation of factor models. Some of these procedures are suited for selecting the number of static factors and others seek to determine the number of dynamic factors. In our simulation designs, we only consider the case where the number of static and dynamic factors is the same, i.e. the two representations are equivalent.

### 2.1 Bai and Ng (2002)

Information criteria select the number of factors which minimizes the variance explained by the idiosyncratic component. The estimated number of factor is:

$$
\begin{equation*}
\hat{k}=\underset{0 \leq k \leq r_{\max }}{\operatorname{argmin}}\left(\left[\frac{1}{N T} \sum_{i=1}^{N} \sum_{t=1}^{T}\left(X_{i, t}-\hat{\lambda}_{i}^{k^{\prime}} \hat{F}_{t}^{k}\right)^{2}\right]+k p(N, T)\right), \tag{4}
\end{equation*}
$$

where $\hat{\lambda}_{i}^{k}$ and $\hat{F}_{t}^{k}$ are the principal components analysis estimators of the factor loadings and factors, when the number of static factors is $k \cdot p(N, T)$ is a penalty function that is used to avoid over-parametrization. The authors provide 16 different specifications of the objective function. The most popular one that we consider in the rest of the paper is the $I C_{p 2}$.

### 2.2 Amengual and Watson (2007)

Assume, in addition to the observational equation (1), that $F_{t}$ follow a finite VAR process:

$$
\begin{equation*}
F_{t}=\sum_{i=1}^{p} \Phi_{i} F_{t-i}+\varepsilon_{t} \tag{5}
\end{equation*}
$$

Let $\eta_{t}$ represents the vector of $q$ common dynamic shocks. The innovation $\varepsilon_{t}$ can be written as $\varepsilon_{t}=G \eta_{t}$, where $G$ is $k x q$ with full column rank. By substitution, we have:

$$
\begin{equation*}
\mathbf{e}_{\mathbf{X t}}=\mathbf{X}_{\mathrm{t}}-\sum_{\mathrm{i}=1}^{\mathrm{p}} \wedge \Phi_{\mathrm{i}} \mathbf{F}_{\mathrm{t}-\mathrm{i}}=\wedge \mathbf{G} \eta_{\mathrm{t}}+\mathbf{e}_{\mathrm{t}} \tag{6}
\end{equation*}
$$

Hence, $e_{X t}$ follows a static factor model with $q$ factors that correspond to the common shocks $\eta_{t}$. In practice, $e_{x t}$ is obtained by the following calculations:

$$
\begin{align*}
& \hat{e}_{X t}^{A}=X_{t}-\sum_{i=1}^{p} \hat{\wedge} \hat{\Phi}_{i} \hat{F}_{t-i},  \tag{7}\\
& \hat{e}_{X t}^{B}=X_{t}-\sum_{i=1}^{p} \hat{\Pi}_{i}^{o l s} \hat{F}_{t-i}, \tag{8}
\end{align*}
$$

where $\hat{F}$ and $\hat{\wedge}$ denote the principal components estimators of $F$ and $\wedge$, using the consistent estimator of $k$, and $\left(\hat{\Phi}_{1}, \hat{,} \Phi_{2}, \ldots, \hat{,} \Phi_{p}\right)$ the ordinary least square estimator of $\hat{F}_{t}$ onto $\left(\hat{F}_{t-1}, \hat{F}_{t-2}, \ldots, \hat{F}_{t-p}\right)$. On the other hand, $\left(\hat{\Pi}_{1}^{\text {ols }}, \Pi_{2}^{\text {ols }}, \ldots, \Pi_{p}^{\text {ols }}\right)$ are the OLS estimators from projection of $X_{t}$ onto $\left(\hat{F}_{t-1}, \hat{F}_{t-2}, \ldots, \hat{F}_{t-p}\right)$.

Finally, the Bai and Ng (2002) $I C_{p 2}$ criteria are applied on an estimate of $e_{X t}$ to select the number of dynamic common shocks. In our exercises, we concentrate only on static factor models so the matrix $G$ is identity, and we will use the estimator in (7).

### 2.3 Onatski (2010)

Onatski (2010) develops an estimator of the number of factors-in the approximated factor models-that performs well even when the idiosyncratic terms are correlated. Assume that the idiosyncratic components of the data can been written as $e=A \varepsilon B$, where A and B are two largely unrestricted matrices and $\varepsilon$ is an $N \times T$ matrix with i.i.d. Gaussian errors. Both (limited) cross-sectional and temporal correlations in $e$ are allowed. Onatski (2010) observes that any finite number of the largest idiosyncratic eigenvalues of the sample covariance matrix clusters around a single point, while all the systematic eigenvalues-the number of which equals the number of factor-diverge to infinity. The estimator then separates the diverging eigenvalues from the cluster and counts the number of separated eigenvalues-this is the estimated number of factors. Bai and Ng (2002), Hallin and Liska (2007), and Amengual and Watson (2007) made the assumption that the factor's cumulative effect on the $N$ cross-sectional units grows proportionally to $N$. According to this assumption, with $r$ static factors, $r$ eigenvalues of the data's covariance matrix grow proportionally to $N$ while the rest of the eigenvalues stay bounded. Onatski (2010) estimates the number of factors without making any assumption on the rate of growth of the factor's cumulative effect.

Let $k$ be the number of factors, and $\lambda_{j}$ the $j$ largest eigenvalues of $X X^{\prime} / T$, Onatski (2010) shows that for $j>\mathrm{k}$, the differences $\lambda_{j}-\lambda_{j+1}$ converge to zero while the differences $\lambda_{k}-\lambda_{k+1}$ diverge to infinity. Let $\left\{k_{\text {max }}^{n}, n \in \mathbb{N}\right\}$ be a slowly increasing sequence of real numbers such that $\left(k_{\max }^{n} / n\right) \rightarrow 0$ as $n \rightarrow \infty$. The family of estimators is defined as:

$$
\hat{k}(\delta)=\max \left\{i \leq k_{\max }^{n}: \lambda_{i}-\lambda_{i+1} \geq \delta\right\},
$$

where $k_{\max }^{n}$ is the maximum possible number of factors having a sample of size $n$.

### 2.4 Ahn and Horenstein (2013)

The idea is based on the fact that the $k$ largest eigenvalues of the variance matrix of $N$ response variables grow unboundedly as $N$ increases, while the other eigenvalues remain bounded. The estimators are obtained by maximizing the ratio of two adjacent eigenvalues. The two estimators are:

$$
\hat{k}_{E R}=\underset{0 \leq k \leq k_{\max }}{\operatorname{argmax}} \frac{\tilde{\mu}_{N T, k}}{\tilde{\mu}_{N T, k+1}}
$$

and

$$
\hat{k}_{G R}=\underset{0 \leq k \leq k_{\max }}{\operatorname{argmax}} \frac{\log [V(k-1) / V(k)]}{\log [V(k) / V(k+1)]},
$$

where $V(k)=\sum_{j=k+1}^{m} \tilde{1}_{N T, j}$ and $\tilde{\mu}_{N T, k}:=\psi_{k}\left[X X^{\prime} /(N T)\right]$ are the $k^{\text {th }}$ largest eigenvalues of the positive semi definite matrix $X X^{\prime} /(N T)$. ER refers to the eigenvalue ratio and GR to the growth ratio.

### 2.5 Bai and Ng (2007)

Bai and $\operatorname{Ng}$ (2007) exploit the fact that if a $r \mathrm{x} r$ matrix $\Sigma_{u}$ has rank $q$, the $k-q$ smallest eigenvalues are zero. Let $c_{1}>c_{2}>\ldots>c_{N}$ be the ordered eigenvalues of $\Sigma_{u}$, and

$$
D_{1 k}=\left(\frac{c_{k+1}^{2}}{\sum_{j=1}^{r} c_{j}^{2}}\right)^{1 / 2} \text { and } D_{2 k}=\left(\frac{\sum_{j=k+1}^{r} c_{k+1}^{2}}{\sum_{j=1}^{r} c_{j}^{2}}\right)^{1 / 2}
$$

When the true eigenvalues $c_{q+1, \ldots}, c_{r}$ are zero, $D_{1 k}$ and $D_{2 k}$ should be zero for any $k>q$. The covariance matrix $\Sigma_{u}$ is estimated by $\hat{\Sigma}_{u}=\frac{1}{T-p} \sum_{t=1}^{T} \hat{u}_{t} \hat{u}_{t}^{\prime}$, where $\hat{u}_{t}$ are the residuals from estimation of the $\operatorname{VAR}(p)$ process in $\hat{F}$. The cut-off point is used to account for estimation error.
2.6 Hallin and Liska (2007)

Let $\sum_{n}(\theta), \quad \theta \in[-\pi, \pi]$ represent the spectral density matrices and $\lambda_{n 1}(\theta), \ldots \lambda_{n n}^{n}(\theta)$ its eigenvalues in decreasing order of magnitude. If the spectral density matrices $\sum_{n}(\theta)$ are known, Hallin and Liska (2007) propose selecting the number of factors as:

$$
\hat{q}_{n}=\underset{0 \leq k \leq q_{\max }}{\operatorname{argmin}}\left[\frac{1}{n} \sum_{j=k+1}^{n} \int_{-\pi}^{\pi} \lambda_{n, j}(\theta) d \theta+k p(n)\right],
$$

where $p(n)$ is a penalty function, and $q_{\max }$ is some predetermined upper bound. In this case, $\hat{q}_{n}$ is deterministic because the spectral density matrices $\sum_{n}(\theta)$ are assumed known. Under assumptions in their paper, if the penalty is such that $\lim _{n \rightarrow \infty} p(n)=0$ and $\lim _{n \rightarrow \infty} n p(n)=\infty$, we have that $\lim _{n \rightarrow \infty} \hat{q}_{n}=q$.

If the spectral density matrices $\sum_{n}(\theta)$ are unknown, they can be estimated by the lag window estimator $\sum_{n}^{T}(\theta)$ :

$$
\sum_{n}^{T}(\theta):=\frac{1}{2 \pi} \sum_{u=-M_{T}}^{M_{T}} w\left(M_{T}^{-1} u\right) \Gamma_{n, u}^{T} e^{-i u \theta}
$$

where $x \rightarrow w(x)$ is a positive even-weight function and $M_{T}>0$ is a truncation parameter, $\Gamma_{n, u}^{T}$ is the sample cross-covariance matrix of $X_{n, t}$ and $X_{n, t-u}$ based on T information.

The estimated factor number, for a given pair $n$ and $T$, are:

$$
\hat{q}_{1, n}^{T}=\underset{0 \leq k \leq q_{\max }}{\operatorname{argmin}}\left[\frac{1}{n} \sum_{i=k+1}^{n} \frac{1}{2 M_{T}+1} \sum_{l=-M_{T}}^{M_{T}} \lambda_{n i}^{T}\left(\theta_{l}\right)+k p(n, T)\right]
$$

or

$$
\hat{q}_{2, n}^{T}=\underset{0 \leq k \leq q_{\max }}{\operatorname{argmin}}\left[\log \left(\frac{1}{n} \sum_{i=k+1}^{n} \frac{1}{2 M_{T}+1} \sum_{l=-M_{T}}^{M_{T}} \lambda_{n i}^{T}\left(\theta_{l}\right)\right)+k p(n, T)\right],
$$

where $p(n, T)$ is a penalty function, $\theta_{l}:=\pi l /\left(M_{T}+1 / 2\right)$ for $l=-M_{T}, \ldots, M_{T}, q_{\max }$ is the predetermined upper bound and the eigenvalues $\lambda_{n i}^{T}\left(\theta_{l}\right)$ are those of the lag window estimator $\sum_{n}^{T}(\theta)$. Under the assumptions in Hallin and Liska (2007), the estimators $\hat{q}_{1, n}^{T}$ and $\hat{q}_{2, n}^{T}$ are consistent.

## 3. Empirical Evidence

Despite a good performance of all selection methods in simulation experiments under regular conditions, their application to large macroeconomic and financial data sets produces mitigated results. In particular, the estimated number of factors varies significantly across the selection procedures and even within a single one.

In this section we compare all the procedures using a variety of macroeconomic and financial panels. A number of conditions can affect the performance of selection methods. First, the macroeconomic panel must be constructed in a way that is representative of economy: time series for different sectors of economic real activities, prices, monetary and credit aggregates, interest rates, etc. The sectoral and disaggregate data are more and more readily available, but adding many series of the same type is not always recommended because it may alter the estimation of common factors, as pointed by Boivin and Ng (2006). The most used US macroeconomic panel is the one from Stock and Watson (2002). While it has been updated by a number of researchers, the core of the data set-in terms of the relative importance of sectors-is always the same. Second, all of these time series must be stationary. In some cases the solution is easy, but in others the transformation

FIGURE 1
Number of Factors over Time: Macroeconomic Panel

to be applied is not obvious. For example, some researchers kept interest rates and inflation rates in levels (Bernanke, Boivin and Eliasz, 2005), while others considered the first difference (Stock and Watson, 2005). Since these series usually represent an important part of the sample, the stationary transformations may substantially modify the correlation structure and hence alter the estimation of the number of factors. Finally, the frequency in which the time series are observed and transformed can be important. Financial indicators are often available on a daily basis while real economic activity series are observed at best monthly. If, in addition, one requires

FIGURE 1 (CONTINUED)

Note: This figure presents the selection of the number of factors during 1980-2012 period. The first column presents results computed for a rolling window with 192 months in size (the initial period is 1964M01-1979M12). The second column presents results for the expanding window where the time series size grows every period. AH2013 stands for Ahn and Horenstein (2013), HL2007 for Hallin and Liska (2007), O2010 for Onatski (2010), AW2007 for Amengual and Watson (2007), BN2002 and BN2007 for Bai and $\mathrm{Ng}(2002,2007)$, respectively. Shaded areas represent the NBER recession periods.
quarterly series such GDP and government spending indicators, the construction of the data set involves several temporal aggregations that are known to change the time series properties (see Lutkepohl, 1984). To investigate the empirical stability of results, we estimate the number of factors in several data sets and across time.

### 3.1 Number of Factors in a Large Panel of Macroeconomic Variables

Figure 1 presents the selection of the number of factors in a large US macroeconomic panel used in Jurado, Ludvigson, and Ng (2013). The data description is available in Appendix B. Essentially, it is an updated version of the Stock-Watson data set, which consists of 132 monthly macroeconomic series observed between 1964M01-2011M12. The data have been stationarized following Stock and Watson (2005): interest, unemployment rates, and inflation measures are in first-difference. We start selecting a number of factors within the 1964M01-1979M12 sub-period and then continue until the end with rolling and expanding windows (first and second column panels, respectively). The first row panels present results for Ahn and Horenstein (2013), Hallin and Liska (2007), and Onatski (2010) procedures while the results for information criteria are presented in the second row. In the case of Bai and Ng (2002), we show the $I C_{p 2}$ criterion, which is also used in the second step of Amengual and Watson (2007).

We remark important instabilities over time and between methods. Firstly, the suggested number of factors varies significantly across the criteria-in the full sample case, at the end of the expanding window, it goes from 1 to 7 . Typically, the estimates of the number of dynamic factors are smaller than those of static factors. Secondly, there is lot of instability over time. For example, consider the Amengual and Watson (2007) criteria in the rolling window panel. The suggested number of factors during the 80 s was stable at 3 , but then rose to 4 and 5 until the 2008-09 recession. A similar behavior is observed in the expanding window exercise.

This figure presents the selection of the number of factors during 1980-2012 period. The first column presents results computed for a rolling window with 192 months in size (the initial period is 1964M01-1979M12). The second column presents results for the expanding window where the time series size grows every period. AH2013 stands for Ahn and Horenstein (2013), HL2007 for Hallin and Liska (2007), O2010 for Onatski (2010), AW2007 for Amengual and Watson (2007), BN2002 and BN2007 for Bai and Ng $(2002,2007)$, respectively. Shaded areas represent the NBER recession periods.

### 3.1.1 Interpretation of Factors

It is well known that the factors are identified up to a rotation. The estimation of $F_{t}$ by principal components of $X_{t}$ specifies a particular rotation matrix such that factors are orthonormal and $\Lambda^{\prime} \Lambda$ is diagonal ${ }^{2}$. However, after the estimation, it is common practice to verify which type of variables loads on each factor. Since we have found that the number of factors is likely to change over time, it is interesting to see if their interpretation remains stable.
2. See Bai and Ng (2013) for more details on identification issues within principal components estimation of factor models

The interpretation of factors is formulated in terms of the marginal $R^{2}$ of each element in $F_{t}$ for all series in $X_{t}$. To fix the ideas, we evaluate separately the part of the variance of each series explained by every factor. Then, we order the series by highest marginal $R^{2}$ s for each factor. We start with the initial period 1964M011979M12 and expand the panel recursively month by month. The results are presented in Figures 3 and 4. Consider, for example, the first north-west panel in Figure 3. The blue line corresponds to the highest marginal $R^{2}$ of the first factor, regardless the series. The five series in the text box are those that load the most on $F_{1}$ during that period, in descending order. This exercise reveals that the variation in the growth rate of the industrial production index of manufacturing industries (IP: mfg ) is explained by more than $82 \%$ by the first factor during 1980, but its explanatory power decreases to $77 \%$ for the full sample. We note that the interpretation of the first factor did not change over time, it is highly related to the real sector, which includes the other series like employment and capital utilization. The explanatory power of the second factor did not change either: it represents the credit spread and the long term spread measures. Its determination coefficient goes from $65 \%$ during the 1980 decade to $55 \%$ at the end of the sample.

On the other hand, the interpretations of the third and the fourth factor have changed through the sample. The vertical lines correspond to periods where the ordering of five most-explained series by the factor has changed. Before 1986, $F_{3}$ was clearly related to the term structure of interest rate, but subsequently became an inflation factor. In addition, its explanatory power has risen significantly over time, especially from the year 1990. On the contrary, the fourth factor was related to prices before 1990 and then became a term structure factor from 1999 onwards. The results for factors five to eight are presented in Figure 4. The fifth factor's interpretation remained quite stable over time-it explains around $35 \%$ of the variation in short term spreads. The sixth factor exhibited an interesting behavior. It is clearly related to the stock markets, with a respectable $R^{2}$ of $30 \%$ for the $\mathrm{S} \& \mathrm{P}$ industrial returns until 1990. However, between 2001 and 2008, it explained almost $60 \%$ of the variation in total reserves growth-clearly making it a monetary factor. Finally, the interpretations of $F_{7}$ and $F_{8}$ have evolved a lot during the 1980-2011 period. In the case of $F_{7}$, it changes from being an exchange rates, inflation, and stock market factor to a housing market factor in 2001.

Now, let us see how the estimated number of factors relates to their interpretations. Consider, for example, the Bai-Ng (2002) criteria at the south-east panel in Figure 1. The estimated number of factors is five until 1984M02. Hence, the underlying states of the economy until 1984 were: real, credit spread, term structure of interest rates, inflation, and term spread. Then, from 1984 to 1991, the estimated $K$ grows to six, implying the following decomposition of elements of $F_{t}$ : real, credit spread, inflation and term structure, term spread, and stock market factors. The ordering is important since $F_{t}$ is estimated by principal components: they are ordered by explanatory power of the total variance of $X_{t}$. Between 1992 and 2001, a seventh factor is suggested by the information criteria. The interpretation from the previous period did not change except that the seventh factor is also related to

FIGURE 2
Number of Factors over Time: Financial Panel

the stock market. Between 2002 and mid-2009, eight factors are needed. Now, the $6^{\text {th }}, 7^{\text {th }}$, and $8^{\text {th }}$ components correspond to monetary aggregates, housing market, and stock market, respectively. Finally, when we consider the full sample, seven factors are estimated.

### 3.2 Number of Factors in a Large Panel of Financial Variables

As noted by Onatski (2012), macroeconomic panels may suffer from a weak factor structure. In fact, macroeconomic aggregates and sectoral data are strongly

FIGURE 2 (CONTINUED)

Note: This figure presents the selection of the number of factors during 1980-2012 period. The first column presents results computed for a rolling window with 240 months in size (the initial period is 1960M01-1979M12). The second column presents results for the expanding window where the time series size grows every period. Shaded areas represent the NBER recession periods.
correlated within groups but less across them. For example, inflation series are very similar amongst each other but much less correlated to employment indicators. The presence of correlation clusters may alter the strength of the common factor structure and hence the estimation of pervasive factors.

The factor analysis has been applied in finance to characterize the determinants of a large set of returns. In this section, we consider a large financial data set from Jurado, Ludvigson, and Ng (2013), which is an update from Ludvigson and Ng (2007). There are 147 financial market variables observed from 1960M01 to 2011M12. The data description is available in Appendix B. Figure 2 shows the selection of the number of factors over time. There is less instability in case of the information criteria on second row panels for both rolling and expanding windows, in comparison to results from the macroeconomic panel in Figure 1. Interestingly, Hallin and Liska (2007) and Onatski (2010) suggest that number of factors varies more, especially for the rolling window. The former seems to be highly unstable since the late 90s while the latter suggests between 1 and 6 factors during 19881998 period.

In the Appendix, we presented more examples with other US and Canadian macroeconomic panels.. Overall, using a battery of selection methods, we find robust evidence that the number of factors is changing over time. One can offer several explanations for this finding. Possibly, if the factors represent the latent states of economy, these could be more or less pervasive over time such that their number is harder to estimate. The structural changes, such as adoption of new monetary and fiscal policies, can also affect the way observable series load on the factors. This hypothesis of structural instability can be represented by time-varying factor loadings. Hence, the number of factors is always the same but a subset of them may become more or less related to the series in $X_{i}$.

This figure presents the selection of the number of factors during 1980-2012 period. The first column presents results computed for a rolling window with 240 months in size (the initial period is 1960M01-1979M12). The second column presents results for the expanding window where the time series size grows every period. Shaded areas represent the NBER recession periods.

In the next section we will investigate if the structural instability in factor loadings can alter the selection of the number of factors. Both exact and approximate factor models will be considered.

## 4. Monte Carlo Simulation Exercise I: Time-varying Factor Loadings

The aim of this simulation is to assess the robustness of different tests and information criteria used when selecting the number of factors in a static factor model. Recall the model:

$$
\begin{aligned}
& \mathbf{X}_{\mathbf{t}}=\wedge_{\mathbf{t}} \mathbf{F}_{\mathbf{t}}+\mathbf{e}_{\mathbf{t}}, \\
& \wedge_{t}=\wedge_{0}+h_{N T} \zeta_{t} .
\end{aligned}
$$

The focus is on instabilities of the factor loadings, $\wedge_{t}$; hence, one needs to impose a stochastic process for them. We consider several cases that can be summarized as follows (see BPSW 2012):

Case 1: The factor loadings do not vary over time.

- $q=2$,
- $(N, T) \in\{(50,100),(100,200)\}$,
- $\wedge_{t}=\wedge_{0}, \forall_{t}$,
- $\lambda_{i, j} \sim N(0,1), F_{j, t} \sim N(0,1), e_{i, t} \sim N(0,1), i=1,, N, j=1,, q$ and $t=1,, T$.

Case 2: The factor loadings are random variables.

- $q=2$,
- $(N, T) \in\{(50,100),(100,200)\}$,
- $F_{j, t} \sim N(0,1), e_{i, t} \sim N(0,1)$,
- $\wedge_{t}=\zeta_{t}$.

For each $t \in\{1 \ldots T\}$ we draw $\lambda_{i, j}, 1 \leq j \leq N$ and $1 \leq i \leq q$ from $N(0,1)$ distribution.

Case 3: Single large deterministic break with $h_{N T}=10$.

- $q=2$,
- $(N, T) \in\{(50,100),(100,200)\}$,
- $\lambda_{i, j} \sim N(0,1), F_{j, t} \sim N(0,1), e_{i, t} \sim N(0,1)$,
- $\wedge_{t}=\left\{\begin{array}{cc}\wedge_{0} & \text { for } t=1, \ldots, T / 2 \\ \wedge_{t}=\wedge_{0}+10 \wedge_{0} & \text { for } t>T / 2\end{array}\right.$.

Case 4: Single small deterministic break with $h_{N T}=1$.

- $q=2$,
- $(N, T) \in\{(50,100),(100,200)\}$,
- $\lambda_{i, j} \sim N(0,1), F_{j, t} \sim N(0,1), e_{i, t} \sim N(0,1)$,
$\cdot \wedge_{t}=\left\{\begin{array}{cc}\wedge_{0} & \text { for } t=1, \ldots, T / 2 \\ \wedge_{t}=\wedge_{0}+\wedge_{0} & \text { for } t>T / 2\end{array}\right.$.
Case 5: Random walk
- $q=2$,
- $(N, T) \in\{(50,100),(100,200)\}$,
- $F_{j, t} \sim N(0,1), e_{i, t} \sim N(0,1)$,
- $\wedge_{t}=\wedge_{t-1}+\zeta_{t}$ where $\left(\zeta_{i, j}\right)_{t} \sim N(0,1)$. The sequence $\wedge_{t}$ at $t=0$ is initialized from $\lambda_{i, j} \sim N(0,1)$.

To complete the simulation exercise, we also consider several degrees of cross-sectional and time dependence among idiosyncratic components in the observational equation, $e_{t}$. In particular, we follow Boivin and Ng (2005), Onatski (2012), and Dufour and Stevanovic (2013). Assuming that

$$
e_{i, t}=\rho_{N} e_{i-1, t}+\zeta_{i, t}
$$

and

$$
\begin{aligned}
& \zeta_{i, t}=\rho_{T} \zeta_{i, t-1}+\varepsilon_{i, t} \\
& \varepsilon_{i, t} \sim N(0,1) .
\end{aligned}
$$

Hence, the parameter $\rho_{N}$ drives the degree of cross-sectional dependence while $\rho_{T}$ is responsible for serial correlation among $e_{i}$. For each factor loadings cases above, following Dufour and Stevanovic (2013), we consider four correlation structures of $e_{t}$ :

- Exact factor structure: $\rho_{N}=0$ and $\rho_{T}=0$,
- Cross-sectional dependence: $\rho_{N}=0.5$ and $\rho_{T}=0$,
- Serial correlation: $\rho_{N}=0$ and $\rho_{T}=0.9$,
- Cross-sectional and serial dependence: $\rho_{N}=0.5$ and $\rho_{T}=0.9$.

In addition, we consider two sets of panel dimensions: $N=50, T=100$ (small sample) and $N=100, T=200$ (large sample).

The Monte Carlo exercise consists of simulating 1000 times for each case, small and large samples, each correlation structure, and then applying all tests or criteria. For each selection procedure, we compute the percentage of underestimation, overestimation, and exact estimation. The mean and standard deviation of estimated number of factors are also computed.

### 4.1 Results and Discussion

The results are summarized in four tables. Table 1 shows the simulation results in the case of exact factor structure. Table 2 presents the performance of selection methods in presence of cross-sectional dependence, while Table 3 presents results where only univariate serial correlation of $e_{t}$ is considered. Lastly, Table 4 shows the behavior of selection methods in the case of the weakest factor structure implied by the presence of both cross-sectional and serial dependence.

Overall, it is most problematic when the factor loadings follow a random walk (case 5). In that case, each test and information criteria fails to capture the true number of factors in both small and large samples and in all four correlation structures of the idiosyncratic component (see Tables 1-4). In particular, Ahn and Horenstein (2013) and Bai and Ng (2007) systematically underestimate the number of factors, while the others largely overestimate.

In the case of classical factor structure, $\rho_{N}=0$ and $\rho_{T}=0$, results summarized in Table 1 show that, having a break on loading factors (cases 3 and 4) does not prevent the identification of the good number of factors in the large sample; however, this is not always the case in the small sample. For example, when there is a high break on loading factors (case 3), Hallin and Liska (2007) underestimate the number of factors at least $16 \%$ of the time, while Amengual and Watson (2007) information criteria overestimate approximately $15 \%$. Hallin and Liska (2007) have the worst record on estimating the true number of factors in a small sample and this may be due to less accuracy in estimating a spectral density with a small amount of data points.

However, as soon as we allow for time and/or cross-sectional dependence, the amplitude of the break increases the probability to undercover the true number of factors. For example, Bai and Ng (2002) information criteria is a perfect estimator when there were no dependence, but overestimates $q$ when allowing for a break. Moreover, as the break becomes larger, the $\hat{q}$ also becomes larger: Table 2 shows that, in the large sample, when the break is 1 the estimated number of factors is three, versus eight when the amplitude of the break is 10. BPSW and Chen, Dolado, and Gonzalo (2014) find similar behavior of the Bai and Ng (2002) information criteria $I C_{p 2}$. Another observation in Table 2 concerns Hallin and Liska (2007). In the large sample, it usually overestimates the number of factors when the magnitude of the break is 10 but performs perfectly when the break is smaller.

Strong time dependence leads many tests and information criteria to fail in identifying $q$ even in the case of constant factor loadings. As expected, the situation is worse in small samples. However, even when the panel dimensions are larger, only Ahn and Horenstein (2013) and Bai and Ng (2007) perform well.

To summarize, the results from this extensive simulation exercise show that structural instabilities, taking several forms of time-variant factor loadings, together with cross-sectional and time dependence of the idiosyncratic component, do alter the estimation of the number of factors across many popular selection methods used in the literature.

## Consequences

Here we discuss several consequences of the previous results for empirical analysis. Diffusion indices have been very popular in forecasting within the factor-augmented regressions. The typical framework consists of the forecasting equation for a series of interest $y_{t}$ :

$$
\begin{equation*}
y_{t+h}=\alpha+\rho y_{t}+\beta F_{t}+\xi_{t+h}, \tag{9}
\end{equation*}
$$

where a large number of potential predictors obey a factor model

$$
X_{t}=\Lambda F_{t}+e_{t}
$$

Hence, the question is how the forecasting performance is affected in the presence of irregularities in the observational equation. Chen, Dolado, and Gonzalo (2014)

Case 1: constant factor loadings. Case 2: factor loadings are random variables. Case 3: single large deterministic break on loadings. Case 4: single small deterministic break on loadings. Case 5: each factor loading follows a random walk.
show, using simulations, that imposing a priori number of factors that ignores the existence of a large break on $\Lambda$ can worsen the forecasting power of the factor-augmented regressions. Overestimating the number of factors can help, but this entails more estimation uncertainty that ultimately increases the mean squared predicted errors. Barhoumi, Darné, and Ferrara (2013) compare several selection methods in the pseudo out-of-sample forecasting exercise and find that setting the number of factors with the Alessi, Barigozzi and Capasso (2010) information criterion (a modification of Bai and Ng , 2002) produces significantly lower squared prediction errors.

Our results contribute to these findings by showing that many selection methods typically overestimate the number of factors. Hence, if they are used to assess the dimension of $F_{t}$ to include in (9), a similar forecasting behavior is expected to occur. More importantly, we showed that there are cases where Ahn-Horenstein (2013) and Bai and Ng (2007) tests underestimate the true number of latent common components. Obviously, this will misspecify the forecasting equation (9) as some important predictors would be omitted.

Another area of interest for factor models is the structural analysis. Since Bernanke, Boivin, and Eliasz (2005), the factor-augmented VAR (FAVAR) approach has been heavily used to identify and estimate the effects of structural shocks (monetary, news, productivity, credit, etc.) on real economy of many countries. The FAVAR model consists of the state-space representation

$$
\begin{align*}
& X_{t}=\Lambda F_{t}+e_{t},  \tag{10}\\
& F_{t}=\Phi(L) F_{t-i}+u_{t} . \tag{11}
\end{align*}
$$

where $u_{t}$ are the reduced-form disturbances related to the structural shocks via $u_{t}=H \varepsilon_{t}$. The objects of interest are impulse responses of $X_{t}$ to the structural shocks $\varepsilon_{t}$

$$
\begin{equation*}
X_{t}=[I-\Phi(L) L]^{-1} H \varepsilon_{t} . \tag{12}
\end{equation*}
$$

Clearly, the misspecification, and particularly the underestimation, of the number of elements in $F_{t}$ will alter both the identification of structural shocks and the estimation of the impulse responses. An extensive study on the consequences on forecasting and structural analysis goes beyond the scope of this paper, but is a part of our research agenda.

## Conclusion

The objective of this paper is to verify the robustness of most important selection methods to identify the number of factors in large data sets. Empirically, we show that, in both large macroeconomic and financial panels, the estimated number of factors varies significantly across time procedures. To provide an explanation of these findings we conduct an extensive Monte Carlo simulation exercise with several time-varying processes for factor loadings in both exact and approximate factor model structures.

The simulation results show that structural instabilities do alter the estimation of the number of factors across all six most popular selection methods used in the literature. Their performance is particularly affected when factor loadings behave as random walks and in the presence of cross-sectional and time dependencies across idiosyncratic components. More research is needed to explore the exact theoretical reasons for the systematic failure of these procedures. In addition, we hope this work will provide a basis for pursuing research on developing new estimators of the factor space rank in the presence of time instabilities.

FIGURE 3

[^1]FIGURE 3 (CONTINUED)

FIGURE 4
Marginal $R^{2}$ of Factors over Time

## FIGURE 4 (CONTINUED)

Note: This figure is the continuation of Figure 3 and presents the marginal $R^{2}$ of factors five to eight from 1980 to 2012. For example, the first north-west panel shows the highest individual marginal $R^{2}$ of the first factor, $F_{1}$.

## APPENDIX

## Appendix A: Additional Empirical Results

Figure 5 shows the estimated number of factors over time for the macroeconomic panel used in Boivin, Giannoni and Stevanovic (2013) which is an update of the data set in Bernanke, Boivin and Eliasz (2005). There are 124 variables observed from 1959M01 to 2009M06. This panel is very similar to the one used by Jurado, Ludvigson and Ng (2013) except for the stationarity assumptions on a subset of series. In this data set, interest, unemployment and inflation rates are supposed stationary, therefore they enter $X_{t}$ in levels, contrary to Jurado, Ludvigson and Ng (2013) where the same series are in first difference of logs. Compared to Figure 1, these stationarity assumptions imply more factors on average over time.

FIGURE 5
Number of Factors over Time: Macroeconomic Panel
from Boivin et al. (2013)

FIGURE 5 (CONTINUED)

Note: This figure presents the selection of the number of factors during 1980-2009 period. The first column results are computed for rolling window of size 251 months (the initial period is $1959 \mathrm{M} 02-1979 \mathrm{M} 12$ ). The second column is for the expanding window where the time series size grows every period. Shaded areas represent the NBER recession periods.

## FIGURE 6

Number of Factors over Time: Canadian Macroeconomic Panel

Figure 6 shows the estimated number of factors over time for a macroeconomic panel of Canadian series. The composition of the panel is very similar to the US data set used in Jurado, Ludvigson and Ng (2013). In addition, the same stationarity assumptions are imposed. There are 124 variables observed from 1981M01 to 2011M12. The Canadian macroeconomic data are typically less available and since the recent reform at Statistics Canada many series are constructed from 1981 only.

FIGURE 6 (CONTINUED)

Note: This figure presents the selection of the number of factors during 1992-2012 period. The first column results are computed for rolling window of size 131 months (the initial period is 1981M01-1991M12). The second column is for the expanding window where the time series size grows every period. Shaded areas represent the Canadian recession periods.

Finally, we combine the previous Canadian data set with the Jurado, Ludvigson and Ng (2013) US panel to construct a very large US-CAN macroeconomic panel containing 246 series for 1981 - 2012 period. The results are presented in Figure 7. Overall, the number of factors seems to grow over time.

## FIGURE 7

Number of Factors over Time: US and Canadian Macroeconomic Panel

FIGURE 7 (CONTINUED)

Note: This figure presents the selection of the number of factors during 1992-2012 period. The first column results are computed for rolling window of size 131 months (the initial period is 1981M01-1991M12). The second column is for the expanding window where the time series size grows every period. Shaded areas represent the Canadian recession periods.

## Appendix B: Data Sets

The transformation codes are: 1 - no transformation; 2 - first difference; 4 - logarithm; 5 - first difference of logarithm; 6 - second difference of logarithm. All US macro series are available from Datastream. The sources of financial data are CRSP and Kenneth French and Monika Piazzesi websites. Canadian macroeconomic series are available at StatCan.

[^1]:    Note: This figure presents the marginal $R^{2}$ of first four factors from 1980 to 2012. For example, the first north-west panel shows the highest individual marginal $\mathrm{R}^{2}$ of the first factor, $F_{1}$. Through all sample, the first factor has the highest marginal contribution to variations in the growth rate of industrial production in manufacturing sector (IP: mfg ). The box contains several most explained series by the first factor, in terms of the marginal $R^{2}$.
